Neal Rouzier responds to the JAMA article on Men and Testosterone

On the first day the JAMA article was released I received 500 emails from physicians and patients requesting my opinion of the article that demonstrated an increase in heart attacks and strokes in men treated with testosterone. Today is the second day and I'm afraid to turn on the computer. First of all this was an observational study that was retrospective in nature and this type of study is fraught with compounding biases that are difficult to control as expressed in the discussion section of this study. A randomized controlled trial (RCT) would have much more power than this type of study. Also the problem with an observation study is that it does not prove causation as would an interventional study in a blinded fashion. Therefore observational studies can't prove causation as well as RCTs and what we should take away from the study is that which the researchers state in the last paragraph, that more studies are necessary before definitive conclusions can be made as to cause and effect. Also, treatment decisions should not be based solely on one study but rather on a trend of studies. Unfortunately the editorial comment section did not express this clearly.

The discussion section of this article mentions that this is the only study that showed this adverse outcome and it was in a select group of individuals. All other studies have shown the opposite outcome, either no effect or protection against heart attacks. Since all other studies show the opposite, and one study does not negate all the other studies, and there were some biases in this study, I would suggest that we do not change anything that we do based on one study with flaws and biases when all other studies demonstrate protection against heart disease and stroke (see attached articles). And this was an observational study which has weaker power than a randomized controlled trial. I'm sure that other experts will voice the same opinion once they review the discussion section of this article as there were many biases and flaws in this study. A review of the index lists the studies that demonstrate protection against heart disease and strokes. In the "Longevity Section" that I present in the Part II course, all of the articles demonstrate improved longevity in those treated with testosterone, but increased morbidity and mortality in those men not treated with testosterone. The WHI study showed that Prempro increased heart attacks and strokes in certain individuals. Subsequent studies have proven that estradiol and progesterone, particularly in younger women, don't. Perhaps there is a confounding problem in older Veterans with cardiovascular disease that is different from other studies. However, as presented in the Part II course, every study that I review (and there are many) demonstrated a significant improvement in longevity and decreased morbidity and mortality in addition to improvement in all cardiovascular risk factors in men treated with testosterone as opposed to control groups treated with placebo (see attached studies).

Had this study been published years ago, and all subsequent studies since then showed protection against cardiovascular disease, then this study would have probably been ignored and forgotten. However, since it is recent, then we tend to believe it and reject all the past studies that showed the exact opposite outcome. Nevertheless, one study does not negate many other studies that show opposite results and benefits. So I will log this study on the negative side for testosterone results but it is the only such study on this side. This is in contrast to all the other studies that show benefit of testosterone administration. It is interesting that this study appears now, just after I gave 2 lectures to a medical academy this past weekend in Las Vegas. The two one hour lectures were on all the studies of both estrogen and testosterone protecting against heart attacks and strokes. These reviews of the world's literature demonstrate all the various mechanisms of benefits of hormones in protecting the heart and brain against heart disease, stroke, dementia, and plaque deposition.

The data and literature is overwhelming in favor of a protective effect of estrogen in women and testosterone in men. This recent study, although interesting and intriguing, does not change any of the evidence that I presented in these lectures nor does it change my treatment strategies. Until more studies demonstrate the same, I will continue to follow the scientific literature that demonstrates benefit. As per the suggestion from the authors, they state that more study is needed to evaluate these results. I recommend to patients and physicians that they continue the same treatment with both estrogen in women and testosterone in men based on all prior studies that show benefit in spite of this one negative study.

Certain statements in the discussion section of the study deserve comment. The authors do note that other trials and meta-analyses do not demonstrate adverse cardiovascular outcomes. The trend so far in the literature has been a protective effect as trials demonstrated that testosterone therapy improves a number of intermediate outcomes and cardiac risk factors. This new JAMA study is the first and only study to demonstrate harm and should therefore be interpreted carefully in light of all the other studies demonstrating opposite results. In addition, the results of this study differ from a similar retrospective VA study by Shores et al that demonstrated a 39% reduction in mortality risk among patients treated with testosterone which again suggests caution in coming to conclusions only based on the present study. Different confounders and biases might account for the discrepancy. Multiple limitations of this study are noted by the authors that certainly can affect outcomes. All in all, it is an interesting study with unexpected results that are in discordance with all other studies and should not influence current therapy, but one that begs for more study.

For those patients and physicians that are unfamiliar with the current literature on testosterone therapy, I have included 3 attachments that review various categories of hormone replacement. First are studies that review mortality in men treated with testosterone compared to control groups. Studies show improved survival in treated men versus untreated men. There are fewer heart attacks, cancer, and reduced mortality in men treated with testosterone (in contrast to the current study). Other studies go on to prove that low levels of testosterone increase morbidity and mortality in contrast to men with testosterone levels in the higher quartiles. Low levels of testosterone are predictive of an increase in all-cause mortality (CAD, CVD, cancer). So where would you like your levels to be? Other studies show that there was no increased risk of cardiac events in men treated with testosterone (in contrast to the current study).

The second attachment lists all the articles that demonstrate all the physiologic benefits of testosterone administration on cholesterol, lipoproteins, insulin sensitivity, diabetes, inflammatory cytokines, endothelial dysfunction, atherosclerosis, blood pressure, memory loss, Alzheimer's disease, mood, strength, energy, muscle mass, fat mass, osteoporosis, ED, sexual function, and all-cause mortality. Do you really want to stop the testosterone based on only one negative study? I'm not! What are the consequences of stopping or not taking it? Read the foregoing.

The third attachment reviews beneficial effects on quality of life as well as disease protection. It is amazing the data on reduction of body fat, insulin levels, diabetes, inflammation, and vascular disease. "Testosterone serves to maintain health in every system of the body." Levels of testosterone in the low to mid-normal range are associated with an increase in illness as listed above." And don't forget (pun intended) the protection against Alzheimer's disease.

Respectfully submitted, Neal Rouzier

Neal Rouzier, M.D. is the medical director of the Preventive Medicine Clinic in Palm Springs, California, which specializes in hormone replacement therapy for both men and women. He is a practicing board certified emergency physician and the former assistant director of a large trauma center in Southern California. After completing his residency in family practice and emergency medicine at UCLA, he practiced emergency medicine for over 30 years.

Dr. Rouzier began researching bio-identical hormone therapy in 1983, when his nursing staff frequently reported personal symptoms that are common in menopause. Since then, he has uncovered over 50 years of medical literature that gives credence to the optimization of hormone levels to treat and prevent the many diseases of aging. Dr. Rouzier is now highly esteemed in the field of age management and lectures to medical academies around the world. He also teaches highly respected and successful courses, demonstrating the protocols derived from evidence-based research and therapeutic application. His four part BHRT Series continues to receive excellent reviews on his practical approach to prescribing, adjusting and monitoring hormone replacement therapy. Dr. Rouzier is the author of How to Achieve Healthy Aging for Men & Women, a popular book on hormone replacement that introduces this concept from a scientific perspective.

Testosterone Treatment and Mortality in Men with Low Testosterone Levels

1. Molly M. Shores,
2. Nicholas L. Smith,
3. Christopher W. Forsberg,
4. Bradley D. Anawalt and
5. Alvin M. Matsumoto

Abstract

Context: Low testosterone levels in men have been associated with increased mortality. However, the influence of testosterone treatment on mortality in men with low testosterone levels is not known.

Objective: The objective of the study was to examine the association between testosterone treatment and mortality in men with low testosterone levels.

Design: This was an observational study of mortality in testosterone-treated compared with untreated men, assessed with time-varying, adjusted Cox proportional hazards regression models. Effect modification by age, diabetes, and coronary heart disease was tested *a priori*.

Setting: The study was conducted with a clinical database that included seven Northwest Veterans Affairs medical centers.

Patients: Patients included a cohort of 1031 male veterans, aged older than 40 yr, with low total testosterone [≤250 ng/dl (8.7 nmol/liter)] and no history of prostate cancer, assessed between January 2001 and December 2002 and followed up through the end of 2005.

Main Outcome Measure: Total mortality in testosterone-treated compared with untreated men was measured.

Results: Testosterone treatment was initiated in 398 men (39%) during routine clinical care. The mortality in testosterone-treated men was 10.3% compared with 20.7% in untreated men ($P<0.0001$) with a mortality rate of 3.4 deaths per 100 person-years for testosterone-treated men and 5.7 deaths per 100 person-years in men not treated with testosterone. After multivariable adjustment including age, body mass index, testosterone level, medical morbidity, diabetes, and coronary heart disease, testosterone treatment was associated with decreased risk of death (hazard ratio 0.61; 95% confidence interval 0.42–0.88; $P = 0.008$). No significant effect modification was found by age, diabetes, or coronary heart disease.

Conclusions: In an observational cohort of men with low testosterone levels, testosterone treatment was associated with decreased mortality compared with no testosterone treatment. These results should be interpreted cautiously because residual confounding may still be a source of bias. Large, randomized clinical trials are needed to better characterize the health effects of testosterone treatment in older men with low testosterone levels.

Clinical Study

Testosterone deficiency is associated with increased risk of mortality and testosterone replacement improves survival in men with type 2 diabetes

1. Vakkat Muraleedharan1,2,
2. Hazel Marsh1,
3. Dheeraj Kapoor1,
4. Kevin S Channer3,4 and
5. T Hugh Jones1,2

Abstract

Objective Men with type 2 diabetes are known to have a high prevalence of testosterone deficiency. No long-term data are available regarding testosterone and mortality in men with type 2 diabetes or any effect of testosterone replacement therapy (TRT). We report a 6-year follow-up study to examine the effect of baseline testosterone and TRT on all-cause mortality in men with type 2 diabetes and low testosterone.

Research design and methods A total of 581 men with type 2 diabetes who had testosterone levels performed between 2002 and 2005 were followed up for a mean period of 5.8 ± 1.3 S.D. years. Mortality rates were compared between total testosterone $>10.4\,nmol/l$ ($300\,ng/dl$; $n=343$) and testosterone $\leq 10.4\,nmol/l$ ($n=238$). The effect of TRT (as per normal clinical practise: 85.9% testosterone gel and 14.1% intramuscular testosterone undecanoate) was assessed retrospectively within the low testosterone group.

Results Mortality was increased in the low testosterone group (17.2%) compared with the normal testosterone group (9%; $P=0.003$) when controlled for covariates. In the Cox regression model, multivariate-adjusted hazard ratio (HR) for decreased survival was 2.02 ($P=0.009$, 95% CI 1.2–3.4). TRT (mean duration 41.6 ± 20.7 months; $n=64$) was associated with a reduced mortality of 8.4% compared with 19.2% ($P=0.002$) in the untreated group ($n=174$). The multivariate-adjusted HR for decreased survival in the untreated group was 2.3 (95% CI 1.3–3.9, $P=0.004$).

Conclusions Low testosterone levels predict an increase in all-cause mortality during long-term follow-up. Testosterone replacement may improve survival in hypogonadal men with type 2 diabetes.

Endogenous Testosterone and Mortality Due to All Causes, Cardiovascular Disease, and Cancer in Men

European Prospective Investigation Into Cancer in Norfolk (EPIC-Norfolk) Prospective Population Study

Abstract

Background— The relation between endogenous testosterone concentrations and health in men is controversial.

Methods and Results— We examined the prospective relationship between endogenous testosterone concentrations and mortality due to all causes, cardiovascular disease, and cancer in a nested case-control study based on 11 606 men aged 40 to 79 years surveyed in 1993 to 1997 and followed up to 2003. Among those without prevalent cancer or cardiovascular disease, 825 men who subsequently died were compared with a control group of 1489 men still alive, matched for age and date of baseline visit. Endogenous testosterone concentrations at baseline were inversely related to mortality due to all causes (825 deaths), cardiovascular disease (369 deaths), and cancer (304 deaths). Odds ratios (95% confidence intervals) for mortality for increasing quartiles of endogenous testosterone compared with the lowest quartile were 0.75 (0.55 to 1.00), 0.62 (0.45 to 0.84), and 0.59 (0.42 to 0.85), respectively ($P<0.001$ for trend after adjustment for age, date of visit, body mass index, systolic blood pressure, blood cholesterol, cigarette smoking, diabetes mellitus, alcohol intake, physical activity, social class, education, dehydroepiandrosterone sulfate, androstanediol glucuronide, and sex hormone binding globulin). An increase of 6 nmol/L serum testosterone ($\approx$1 SD) was associated with a 0.81 (95% confidence interval 0.71 to 0.92, $P<0.01$) multivariable-adjusted odds ratio for mortality. Inverse relationships were also observed for deaths due to cardiovascular causes and cancer and after the exclusion of deaths that occurred in the first 2 years.

Conclusions— In men, endogenous testosterone concentrations are inversely related to mortality due to cardiovascular disease and all causes. Low testosterone may be a predictive marker for those at high risk of cardiovascular disease.

Abstract

Context: Low testosterone is associated with all-cause mortality, but the relationship with cause-specific mortality is uncertain.

Objective: Our objective was to explore associations between testosterone and its related hormones and cause-specific mortality.

Design: This was a population-based cohort study.

Setting and Participants: Demographic and clinical predictors of mortality, and testosterone, SHBG, and LH were measured from 2001–2004 in 3637 community-dwelling men aged 70–88 yr (mean, 77 yr).

Main Outcome Measure: Cause of death was obtained via electronic record linkage until December 31, 2008.

Results: During a mean follow-up period of 5.1 yr, there were 605 deaths. Of these, 207 [34.2%; 95% confidence interval (CI) = 30.4–38.1%] were due to cardiovascular disease (CVD), 231 to cancer (38.2%; 95% CI = 34.3–42.1%), 130 to respiratory diseases (21.5%; 95% CI = 18.2–24.8%), and 76 to other causes (12.6%; 95% CI = 9.9–15.2%). There were 39 deaths attributable to both cancer and respiratory diseases. Lower free testosterone (hazard ratio = 1.62; 95% CI = 1.20–2.19, for 100 vs. 280 pmol/liter), and higher SHBG and LH levels were associated with all-cause mortality. In cause-specific analyses, lower free testosterone (sub-hazard ratio = 1.71; 95% CI = 1.12–2.62, for 100 vs. 280 pmol/liter) and higher LH predicted CVD mortality, while higher SHBG predicted non-CVD mortality. Higher total testosterone and free testosterone levels (sub-hazard ratio = 1.96; 95% CI = 1.14–3.36, for 400 vs. 280 pmol/liter) were associated with mortality from lung cancer.

Conclusions: Low testosterone predicts mortality from CVD but is not associated with death from other causes. Prevention of androgen deficiency might improve cardiovascular outcomes but is unlikely to affect longevity otherwise.

Since time immemorial, the ability to resist the effects of aging and prolong life has been a universal human desire. For millennia, alchemists sought in vain for an elixir of life, while more recently, 19th-century physicians attempted to produce a rejuvenating tonic from animal testicular extracts (1).

REVIEW

Hypogonadism as a risk factor for cardiovascular mortality in men: a meta-analytic study

Giovanni Corona[1,2], Giulia Rastrelli[1], Matteo Monami[3], André Guay[4], Jaques Buvat[5], Alessandra Sforza[2], Gianni Forti[6], Edoardo Mannucci[3] and Mario Maggi[1]

Abstract

Objective To verify whether hypogonadism represents a risk factor for cardiovascular (CV) morbidity and mortality and to verify whether testosterone replacement therapy (TRT) improves CV parameters in subjects with known CV diseases (CVDs).

Design Meta-analysis.

Methods An extensive Medline search was performed using the following words 'testosterone, CVD, and males'. The search was restricted to data from January 1, 1969, up to January 1, 2011.

Results Of the 1178 retrieved articles, 70 were included in the study. Among cross-sectional studies, patients with CVD have significantly lower testosterone and higher 17-β estradiol (E_2) levels. Conversely, no difference was observed for DHEAS. The association between low testosterone and high E_2 levels with CVD was confirmed in a logistic regression model, after adjusting for age and body mass index (hazard ratio (HR)=0.763 (0.744–0.783) and HR=1.015 (1.014–1.017), respectively, for each increment of total testosterone and E_2 levels; both $P<0.0001$). Longitudinal studies showed that baseline testosterone level was significantly lower among patients with incident overall– and CV–related mortality, in comparison with controls. Conversely, we did not observe any difference in the baseline testosterone and E_2 levels between case and controls for incident CVD. Finally, TRT was positively associated with a significant increase in treadmill test duration and time to 1 mm ST segment depression.

Conclusions Lower testosterone and higher E_2 levels correlate with increased risk of CVD and CV mortality. TRT in hypogonadism moderates metabolic components associated with CV risk. Whether low testosterone is just an association with CV risk, or an actual cause-effect relationship, awaits further studies.

Abstract

Context: Low testosterone levels have been associated with outcomes that reduce survival in men.

Objective: Our objective was to perform a systematic review and meta-analysis of published studies to evaluate the association between endogenous testosterone and mortality.

Data Sources: Data sources included MEDLINE (1966 to December 2010), EMBASE (1988 to December 2010), and reference lists.

Study Selection: Eligible studies were published English-language observational studies of men that reported the association between endogenous testosterone and all-cause or cardiovascular disease (CVD) mortality. A two-stage process was used for study selection. 1) Working independently and in duplicate, reviewers screened a subset (10%) of abstracts. Results indicated 96% agreement, and thereafter, abstract screening was conducted in singlicate. 2) All full-text publications were reviewed independently and in duplicate for eligibility.

Data Extraction: Reviewers working independently and in duplicate determined methodological quality of studies and extracted descriptive, quality, and outcome data.

Data Synthesis: Of 820 studies identified, 21 were included in the systematic review, and 12 were eligible for meta-analysis [n = 11 studies of all-cause mortality (16,184 subjects); n = 7 studies of CVD mortality (11,831 subjects)]. Subject mean age and testosterone level were 61 yr and 487 ng/dl, respectively, and mean follow-up time was 9.7 yr. Between-study heterogeneity was observed among studies of all-cause ($P < .001$) and CVD mortality ($P = 0.06$), limiting the ability to provide valid summary estimates. Heterogeneity in all-cause mortality (higher relative risks) was observed in studies that included older subjects ($P = 0.020$), reported lower testosterone levels ($P = 0.018$), followed subjects for a shorter time period ($P = 0.010$), and sampled blood throughout the day ($P = 0.030$).

Conclusion: Low endogenous testosterone levels are associated with increased risk of all-cause and CVD death in community-based studies of men, but considerable between-study heterogeneity, which was related to study and subject characteristics, suggests that effects are driven by

Low serum testosterone, arterial stiffness and mortality in male haemodialysis patients

Abstract

Background. In the general population, accumulating data support a link between low testosterone levels and mortality by all causes, but especially by cardiovascular disease (CVD). Also, accelerated arterial stiffness has been recognized as an important cardiovascular risk factor. Here, we explored the association between testosterone levels and risk of death in male haemodialysis (HD) patients, whose arterial system is characterized by generalized stiffening.

Methods. In this three-centre prospective observational study, 111 male HD patients after completion of baseline assessment, including measurement of male sex hormones and pulse wave velocity (PWV), were followed up for CVD and all-cause mortality.

Results. Of the 111 patients studied, 54 were found with and 57 without testosterone deficiency, defined as testosterone levels <8 nmol/L. During a median follow-up period of 37 months, 49 deaths occurred, 28 (57%) of which were caused by CVD. Testosterone deficiency patients had increased CVD and all-cause mortality {crude hazard ratio: 3.14 [95% confidence interval (CI), 1.21-8.16] and 3.09 (95% CI, 1.53-6.25), respectively}, even after adjustment for age, body mass index, serum albumin and C-reactive protein, prevalent CVD and HD vintage. The association of testosterone with CVD mortality, but not with all-cause mortality, was lost after adjusting for PWV, an index of arterial stiffness. Testosterone levels were inversely related to PWV ($r = -0.441$; $P < 0.001$).

Conclusion. We showed that testosterone deficiency in male HD patients is associated with increased CVD and all-cause mortality and that increased arterial stiffness may be a possible mechanism explaining this association.

Testosterone deficiency syndrome (TDS) and the heart

This editorial refers to 'Low testosterone levels are associated with increased risk of mortality in a population-based cohort of men aged 20-79'†, by R. Haring *et al.*, on page 1494

A low testosterone [hypogonadism or testosterone deficiency syndrome (TDS)] may be present in 30% of men and present in a number of different ways.[1] One of the problems in detecting TDS is the lack of awareness of its existence amongst the general medical community including cardiologists. In addition, the signs and symptoms may unhelpfully not be specific to TDS (*Table 1*). With the accumulating evidence of an association between TDS and cardiovascular co-morbidities and an increased risk of mortality when compared with men with normal testosterone levels, there is a compelling need to screen men at risk of low testosterone levels.[2]

View this table:
In this window   In a new window

Table 1
Signs and symptoms indicative of TDS

There is increasing evidence that TDS is associated with all-cause mortality and in particular cardiovascular death. Haring and colleagues add to the growing evidence of the importance of a link in a prospective population-based study (mean follow-up 7.2 years) showing in a sample of men aged 20-79 years that a testosterone level <8.7 nmol/L (250 ng/dL) doubled the risk of all-cause mortality independently of age, waist circumference, cigarette smoking, excess alcohol, and decreased physical activity.[3]

A recent observational prospective study from Florence investigated the relationship between low total testosterone levels in 1687 men with erectile dysfunction (ED) and fatal or non-fatal major adverse cardiovascular events (MACEs).[4] Men with a testosterone <8 nmol/L (230 ng/dL), after adjusting for age and chronic diseases, at a mean follow-up of 4.3 ± 2.6 years had a significantly increased incidence of fatal MACEs [hazard ratio (HR) = 7.1 95% confidence interval (CI) (1.8-28.6), P <0.001). In the 6 year CHIANTI study, the same unit suggested that declining testosterone levels were a strong independent predictor of mortality in men.[5]

The EPIC-Norfolk (European Prospective Investigation into Cancer in Norfolk) study performed in the UK was a nested case-control study designed to evaluate any association between testosterone levels and all-cause cardiovascular disease (CVD) and death from cancer.[6] During follow-up, 1489 men lived from entry between 1993 and 1997 to 2003

Oxford Index   About the Index   ▣ vidence of

░░░░░░░░   Show related links ▣   Search across all sources in Oxford Index   ▣

and controls were matched for age and date of baseline visit. Total testosterone concentrations at baseline were found to be inversely related to all-cause mortality ($n = 825$), CVD deaths ($n = 369$), and deaths from cancer ($n = 304$). After adjusting for confounding variables, an increase of 6 nmol/L (173 ng/dL) in serum testosterone was associated with a 14% decrease in death rate regardless of age (above or below 65 years of age). Men in the highest testosterone quartile had a 30% lower risk of death compared with those in the lowest. As occult illness at entry may have distorted the findings, in an additional analysis all those who died in the first 2 years of the study were excluded and the findings were unchanged. The study can be criticized for only including a single testosterone sample and not free or bioavailable testosterone which binds to the androgen receptor, but single measures are believed to be accurate for population studies.[7]

The Rancho-Bernardo area study prospectively followed up 794 men aged 50-91 years, evaluating the link between testosterone levels and all-cause mortality over a 20 year period.[8] Men in the lowest quartile of testosterone levels were 40% more likely to die than those in the highest quartile—mainly from CVD and respiratory disease. These findings were independent of age, obesity, hyperlipidaemia, and lifestyle, and were in line with the Norfolk study. The authors concluded that low testosterone levels (<12.5 nmol/L) could be a predictive marker for men at high risk of CVD.

In a retrospective study of 858 male veterans over 40 years of age without a diagnosis of prostate cancer, ~20% had total testosterone levels <10.4 nmol/L (300 ng/dL) and the survival rate decreased, as did the testosterone level (HR 1.88; 95% CI 1.34-2.63; P <0.001) after adjustments for clinical co-variables over an 8 year period.[9]

Whilst some cross-sectional and prospective studies have found no significant relationship between testosterone levels and CVD, the evidence overall, particularly from the large recent studies, does point to testosterone having a pathogenic role in CVD.[2,10] As TDS is associated with type 2 diabetes, metabolic syndrome, visceral fat accumulation, abnormalities of coagulation, inflammatory cytokines, and dyslipidaemia, its importance is clearly integral to other CVD risk factors.[2,10,11]

Whilst there is no evidence that testosterone replacement reduces CVD risk or all-cause mortality (randomized trials are needed), we have good evidence that replacement may be symptomatically beneficial in hypogonadic men with angina or heart failure.[12,13] Importantly, there is no evidence that replacement increases CVD risk.

In practice consider measuring testosterone (before 11 a.m. to avoid diurnal variation) in those who appear symptomatic or have a chronic illness or erectile dysfunction.[14] Total testosterone levels <8 nmol/L (2.31 ng/mL) or free testosterone (not bound to sex hormone-binding globulin and non-bioavailable, therefore a more accurate but more expensive measurement) <180 pmol/L (52 pg/mL) require replacement therapy.[15] Total levels >12 nmol/L (3.46 ng/mL) or free testosterone levels >250 pmol/L (72 pg/mL) do not, and a trial of therapy can be considered in between 8 and 12 nmol/L total testosterone. Though the link between testosterone replacement and prostate cancer is not proven, monitoring prostate-specific antigen is currently advised and urological advice sought where appropriate. Regular checks on liver function (toxicity is very rare) and polycythaemia are also advised and caution advocated in men with sleep apnoea which may worsen.[14] Oligospermia or azoospermia which may not be reversible can occur, so it is important to check men who wish to preserve their fertility. Monitoring response to replacement therapy should be at 3-6 month intervals.

TDS can symptomatically benefit from replacement therapy which is safe

Abstract

Aims Although the association of low serum testosterone levels with
mortality has gained strength in recent research, there are few
population-based studies on this issue. This study examined whether low
serum testosterone levels are a risk factor for all-cause or cause-specific
mortality in a population-based sample of men aged 20-79.

Methods and results We used data from 1954 men recruited for the
prospective population-based Study of Health in Pomerania, with
measured serum testosterone levels at baseline and 195 deaths during
an average 7.2-year follow-up. A total serum testosterone level of less
than 8.7 nmol/L (250 ng/dL) was classified as low. The relationships of
low serum testosterone levels with all-cause and cause-specific mortality
were analysed by Cox proportional hazards regression models. Men with
low serum testosterone levels had a significantly higher mortality from all
causes than men with higher serum testosterone levels (HR 2.24; 95% CI
1.41-3.57). After adjusting for waist circumference, smoking habits,
high-risk alcohol use, physical activity, renal insufficiency, and levels of
dehydroepiandrosterone sulfate, low serum testosterone levels continued
to be associated with increased mortality (HR 2.32; 95% CI 1.38-3.89). In
cause-specific analyses, low serum testosterone levels predicted
increased risk of death from cardiovascular disease (CVD) (HR 2.56; 95%
CI 1.15-6.52) and cancer (HR 3.46; 95% CI 1.68-6.68), but not from
respiratory diseases or other causes.

Conclusion Low serum testosterone levels were associated with an
increased risk of all-cause mortality independent of numerous risk
factors. As serum testosterone levels are inversely related to mortality
due to CVD and cancer, it may be used as a predictive marker.

Abstract

Context: Declining testosterone levels in elderly men are thought to underlie many of the symptoms and diseases of aging; however, studies demonstrating associations of low testosterone with clinical outcomes are few.

Objective: The objective of the study was to examine the association of endogenous testosterone levels with mortality in older community-dwelling men.

Design, Setting, and Participants: This was a prospective, population-based study of 794 men, aged 50–91 (median 73.6) yr who had serum testosterone measurements at baseline (1984–1987) and were followed for mortality through July 2004.

Main Outcome Measure: All-cause mortality by serum testosterone level was measured.

Results: During an average 11.8-yr follow-up, 538 deaths occurred. Men whose total testosterone levels were in the lowest quartile (<241 ng/dl) were 40% [hazards ratio (HR) 1.40; 95% confidence interval (CI) 1.14–1.71] more likely to die than those with higher levels, independent of age, adiposity, and lifestyle. Additional adjustment for health status markers, lipids, lipoproteins, blood pressure, glycemia, adipocytokines, and estradiol levels had minimal effect on results. The low testosterone-mortality association was also independent of the metabolic syndrome, diabetes, and prevalent cardiovascular disease but was attenuated by adjustment for IL-6 and C-reactive protein. In cause-specific analyses, low testosterone predicted increased risk of cardiovascular (HR 1.38; 95% CI 1.02–1.85) and respiratory disease (HR 2.29; 95% CI 1.25–4.20) mortality but was not significantly related to cancer death (HR 1.34; 95% CI 0.89–2.00). Results were similar for bioavailable testosterone.

Conclusions: Testosterone insufficiency in older men is associated with increased risk of death over the following 20 yr, independent of multiple risk factors and several preexisting health conditions.

Abstract

Background—Low testosterone is an independent predictor of reduced exercise
capacity and poor clinical outcomes in patients with heart failure (HF). We sought
to determine whether testosterone therapy improves exercise capacity in patients
with stable chronic HF.

Methods and Results—We searched Medline, Embase, Web of Science, and
Cochrane Central Register of Controlled Trials (1980-2010). Eligible studies
included randomized controlled trials (RCTs) reporting the effects of testosterone
on exercise capacity in patients with HF. Reviewers determined the methodological
quality of studies and collected descriptive, quality, and outcome data. Four trials
(n=198; men, 84%; mean age, 67 years) were identified that reported the 6-minute
walk test (2 RCTs), incremental shuttle walk test (2 RCTs), or peak oxygen
consumption (2 RCTs) to assess exercise capacity after up to 52 weeks of
treatment. Testosterone therapy was associated with a significant improvement in
exercise capacity compared with placebo. The mean increase in the 6-minute walk
test, incremental shuttle walk test, and peak oxygen consumption between the
testosterone and placebo groups was 54.0 m (95% CI, 43.0-65.0 m), 46.7 m (95%
CI, 12.6-80.9 m), and 2.70 mL/kg per min (95% CI, 2.68-2.72 mL/kg per min),
respectively. Testosterone therapy was associated with a significant increase in
exercise capacity as measured by units of pooled SDs (net effect, 0.52 SD; 95% CI,
0.10-0.94 SD). No significant adverse cardiovascular events were noted.

Conclusions—Given the unmet clinical needs, testosterone appears to be a
promising therapy to improve functional capacity in patients with HF. Adequately
powered RCTs are required to assess the benefits of testosterone in this high-risk
population with regard to quality of life, clinical events, and safety.

Plasma Total Testosterone and Incident Cardiovascular Events in Hypertensive Patients

Abstract

BACKGROUND Androgen deficiency confers an independent risk for
cardiovascular events and total mortality. Hypertension, a major
contributory factor to the development of cardiovascular disease, has
also been associated with increased prevalence of low testosterone. We
investigated whether low androgen concentration predicts incident major
adverse cardiovascular events (MACE) in middle-aged nondiabetic
hypertensive patients without clinical atherosclerosis.

METHODS MACE in relation to total testosterone (TT) were analyzed with
proportional hazards models in 228 male patients (mean age 56 years).

RESULTS During a mean follow-up of 44 months, 19 of 228 participants
(8.3%) experienced a MACE. Compared to patients who did not experience
MACE, hypertensive subjects who developed MACE had lower TT
concentration (3.9 ± 0.7ng/ml vs. 4.6 ± 1.5ng/ml, $P < 0.01$) and a higher
prevalence of hypogonadism (36% vs. 16%, $P < 0.05$). Subjects in the
lowest TT tertile (<4.0ng/ml) had a statistically significant higher risk of
MACE compared to those in the highest tertile (>4.9ng/ml) in
multivariate Cox models adjusted for age, systolic blood pressure, and
risk factors (all $P < 0.05$). A TT plasma level of 5.04ng/ml was associated
with a negative predictive value (ability to "rule out" MACE) of 97.2%.
Addition of TT to standard risk factors model yielded a net
reclassification improvement of 38.8 % ($P < 0.05$).

CONCLUSIONS Our results show that low plasma testosterone is
associated with increased risk for a MACE in hypertensive patients. Low
endogenous androgen concentration improves risk prediction when
added to standard risk factors and may represent a valuable biomarker of
prediction of cardiovascular disease risk in these patients.

Abstract

Aims Accumulating evidence suggests that androgen deficiency is
associated with cardiovascular disease. We aimed at evaluating whether
total testosterone (TT) and free testosterone (FT) are associated with
specific cardiovascular events.

Methods and results We measured TT and sex-hormone-binding
globulin levels in 2078 men who were routinely referred for coronary
angiography between 1997 and 2000. Free testosterone was calculated
according to Vermeulen. Main outcome measures were Cox proportional
hazard ratios (HRs) for sudden cardiac death, fatal myocardial infarction,
death from congestive heart failure (CHF), as well as other cardiac deaths
according to quartiles of TT and FT. The median follow-up time was 7.7
years. Multivariable adjusted HRs (with 95% confidence intervals) in the
fourth compared with the first FT quartile and per 1 SD increase in FT for
CHF mortality were 0.38 (0.17-0.87) and 0.37 (0.15-0.89), respectively.
We observed no independent significant association of FT with sudden
cardiac death, fatal myocardial infarction, or other cardiac death. There
was no independent association of TT levels with cardiovascular events or
cardiac disease.

Conclusion Low levels of FT are independently associated with increased
CHF mortality.

SIR—In men ageing is associated with a gradual progressive decline of total serum testosterone concentration [1–5]. A substantial proportion of older men, ranging from 20% in 60 years old to 50% in 80 years old, have testosterone concentrations below the normal range of younger men [4]. Low testosterone associates with occurrence of various cardiovascular risk factors [6, 7], and most epidemiological studies suggest that association of testosterone with coronary artery disease is either favourable or neutral [8]. Some studies have suggested that leptin is also an independent predictor of cardiovascular morbidity and mortality [9–11], but this association has not been seen in all studies [12]. After adjustment for age, concentration of testosterone in serum is inversely correlated with intima–media thickness of the carotid artery, whereas no such association is seen between serum leptin and carotid artery thickness [12]. Thus, endogenous testosterone may have a protective role in the development of atherosclerosis in ageing men, but information on associations between testosterone and mortality or coronary heart disease is lacking.

We performed a longitudinal 10-year study to clarify the association of endogenous testosterone and leptin with all-cause mortality in ageing men. The results suggest an association between low endogenous testosterone concentration and mortality in elderly men.

Abstract

Objective Men with type 2 diabetes are known to have a high prevalence of testosterone deficiency. No long-term data are available regarding testosterone and mortality in men with type 2 diabetes or any effect of testosterone replacement therapy (TRT). We report a 6-year follow-up study to examine the effect of baseline testosterone and TRT on all-cause mortality in men with type 2 diabetes and low testosterone.

Research design and methods A total of 581 men with type 2 diabetes who had testosterone levels performed between 2002 and 2005 were followed up for a mean period of 5.8 ± 1.3 S.D. years. Mortality rates were compared between total testosterone $>10.4\,nmol/l$ (300 ng/dl; $n=343$) and testosterone $\leq 10.4\,nmol/l$ ($n=238$). The effect of TRT (as per normal clinical practise: 85.9% testosterone gel and 14.1% intramuscular testosterone undecanoate) was assessed retrospectively within the low testosterone group.

Results Mortality was increased in the low testosterone group (17.2%) compared with the normal testosterone group (9%; $P=0.003$) when controlled for covariates. In the Cox regression model, multivariate-adjusted hazard ratio (HR) for decreased survival was 2.02 ($P=0.009$, 95% CI 1.2–3.4). TRT (mean duration 41.6 ± 20.7 months; $n=64$) was associated with a reduced mortality of 8.4% compared with 19.2% ($P=0.002$) in the untreated group ($n=174$). The multivariate-adjusted HR for decreased survival in the untreated group was 2.3 (95% CI 1.3–3.9, $P=0.004$).

Conclusions Low testosterone levels predict an increase in all-cause mortality during long-term follow-up. Testosterone replacement may improve survival in hypogonadal men with type 2 diabetes.

Relationship Between Low Levels of Anabolic Hormones and 6-Year Mortality in Older Men

The Aging in the Chianti Area (InCHIANTI) Study

Marcello Maggio, MD; Fulvio Lauretani, MD; Gian Paolo Ceda, MD; Stefania Bandinelli, MD; Shari M. Ling, MD; E. Jeffrey Metter, MD; Andrea Artoni, MD; Laura Carassale, MD; Anna Cazzato, MD; Graziano Ceresini, MD; Jack M. Guralnik, MD; Shehzad Basaria, MD; Giorgio Valenti, MD; Luigi Ferrucci, MD, PhD

Background Aging in men is characterized by a progressive decline in levels of anabolic hormones, such as testosterone, insulinlike growth factor 1 (IGF-1), and dehydroepiandrosterone sulfate (DHEA-S). We hypothesized that in older men a parallel age-associated decline in bioavailable testosterone, IGF-1, and DHEA-S secretion is associated with higher mortality independent of potential confounders.

Methods Testosterone, IGF-1, DHEA-S, and demographic features were evaluated in a representative sample of 410 men 65 years and older enrolled in the Aging in the Chianti Area (InCHIANTI) study. A total of 126 men died during the 6-year follow-up. Thresholds for lowest-quartile definitions were 70 ng/dL (to convert to nanomoles per liter, multiply by 0.0347) for bioavailable testosterone, 63.9 ng/mL (to convert to nanomoles per liter, multiply by 0.131) for total IGF-1, and 50 µg/dL (to convert to micromoles per liter, multiply by 0.027) for DHEA-S. Men were divided into 4 groups: no hormone in the lowest quartile (reference) and 1, 2, and 3 hormones in the lowest quartiles. Kaplan-Meier survival and Cox proportional hazards models adjusted for confounders were used in the analysis.

Results Compared with men with levels of all 3 hormones above the lowest quartiles, having 1, 2, and 3 dysregulated hormones was associated with hazard ratios for mortality of 1.47 (95% confidence interval [CI], 0.88-2.44), 1.85 (95% CI, 1.04-3.30), and 2.29 (95% CI, 1.12-4.68), respectively (test for trend, $P < .001$). In the fully adjusted analysis, only men with 3 anabolic hormone deficiencies had a significant increase in mortality (hazard ratio, 2.44; 95% CI, 1.09-5.46) (test for trend, $P < .001$).

Conclusions Age-associated decline in anabolic hormone levels is a strong independent predictor of mortality in older men. Having multiple hormonal deficiencies rather than a deficiency in a single anabolic hormone is a robust biomarker of health status in older persons.

Perspectives
Welcoming low testosterone as a cardiovascular risk factor

M Maggio[1] and S Basaria[2]

[1]Department of Internal Medicine, Division of Endocrinology & Metabolism, University of Parma, Parma, Italy and
[2]Department of Internal Medicine, Division of Endocrinology & Metabolism, Boston University School of Medicine,
Boston, MA, USA

Male hypogonadism now has a new spectrum of complications. They are mainly cardiometabolic in
nature. Low serum testosterone levels are a risk factor for diabetes, metabolic syndrome,
inflammation and dyslipidemia. These metabolic and inflammatory complications are not without
consequences. Recent studies have shown low serum testosterone levels to be an independent risk
factor of cardiovascular and all-cause mortality. It is time to welcome low serum testosterone levels
as a cardiovascular risk factor.
International Journal of Impotence Research (2009) **21**, 261–264; doi:10.1038/ijir.2009.25;
published online 18 June 2009

Testosterone is the predominant sex hormone in man. A young man produces 3–10 mg of testosterone daily that results in serum levels of 300–1000 ng per 100 ml. The traditional consequences of male hypogonadism are well known. These include decreased libido, erectile dysfunction, decreased muscle mass and strength, increased fat mass, changes in mood and energy, osteoporosis and decreased sexual hair.[1] However, for the past two decades, many studies have found an association between low serum testosterone levels and various cardiovascular (CV) risk factors. In addition, some epidemiological studies have also linked low testosterone levels with CV and all-cause mortality. In this review, we will briefly touch upon the various CV risk factors that have been linked to low serum testosterone in men.

Diabetes and metabolic syndrome

Low testosterone levels have been associated with diabetes and metabolic syndrome. Epidemiological studies have reported that low testosterone levels are an independent risk factor for type-2 diabetes.[2] Interestingly, concentrations of free and bioavailable testosterone even in the low-normal range are associated with diabetes, after adjusting for adiposity.[3] Similarly, low total testosterone levels independently predict development of the metabolic syndrome in middle-aged men.[4] Interventional trials have shown that testosterone administration results in an increased glucose uptake by the muscles, thereby improving insulin sensitivity.[5] One study even showed an improvement in HbA1c in hypogonadal men with type-2 diabetes who received testosterone.[6] Another study showed that testosterone replacement inhibits incorporation of triglycerides in visceral fat (which is the most active depot metabolically and contributes to insulin resistance).[7] In addition, androgen deprivation in men with prostate cancer is associated with hyperglycemia and metabolic syndrome,[8,9] and the degree of hyperglycemia is directly related to the duration of castration.[10] Thus, even low-normal levels of testosterone appear to be a risk factor for metabolic dysregulation.

Hyperlipidemia and inflammation

In contrast to the belief of many physicians that androgen administration leads to an adverse lipid profile, research shows that physiological testosterone replacement is at least neutral (if not beneficial) to lipids. Hence, it should be differentiated from non-aromatizable androgens that do result in harm-

E-mail: shehzad.basaria@bmc.org

ful lipid profile by lowering high-density lipo-protein. Epidemiological data suggest that testo-sterone levels are associated negatively with total cholesterol, low-density lipoprotein cholesterol and triglycerides, and positively with high-density lipo-protein cholesterol.[11] Trials of testosterone replace-ment have shown an improvement in lipid profile.[12] Similarly, there are reports of inverse associations between inflammatory cytokines and testosterone,[13] and a reduction in these cytokines is seen with testosterone replacement.[12] Furthermore, inverse associations have been found between testosterone and plasminogen activator inhibitor I, fibrinogen and factor VII.[14]

Figure 1 Action of testosterone on calcium and potassium channels.

Atherosclerosis

Studies show that low testosterone levels are associated with atherosclerosis in all major vessels. Animal experiments have shown that testosterone inhibits plaque development in rabbits and rodents fed a high-fat diet.[15] It was Phillips et al.[16] who first reported an inverse relationship between low total and free testosterone levels and angiographically proven coronary artery disease after adjusting for age and adiposity. A recent study confirmed these findings, showing that men with coronary artery disease had lower levels of testosterone than con-trols and that testosterone levels were inversely correlated to the degree of coronary atherosclero-sis.[17] In the Rotterdam study, the association between total and bioavailable testosterone and aortic atherosclerosis was evaluated in 504 non-smoking men aged $\geqslant 55$ years.[14] They found that men in the highest tertile had a risk reduction of 60–80% of severe aortic atherosclerosis after controlling for age and CV risk factors. Another prospective study of elderly men (mean age 77 years) showed free testosterone to be inversely related to the progression of intima–media thickness of the com-mon carotid artery over 4 years.[18] Furthermore, men in the lowest tertile of testosterone experienced more progression.

Vascular tone and endothelial function

The vascular system is a target of androgen action and current evidence suggests that androgens are beneficial to vasculature. Older studies conducted more than six decades ago showed that testosterone replacement relieved symptoms of angina and peripheral vascular disease.[19] Similarly, population studies have shown that systolic and diastolic blood pressures are inversely correlated with testo-sterone.[20] Recent animal studies show that acute treatment with testosterone results in dilatation of the coronary and pulmonary arteries.[21] In humans,
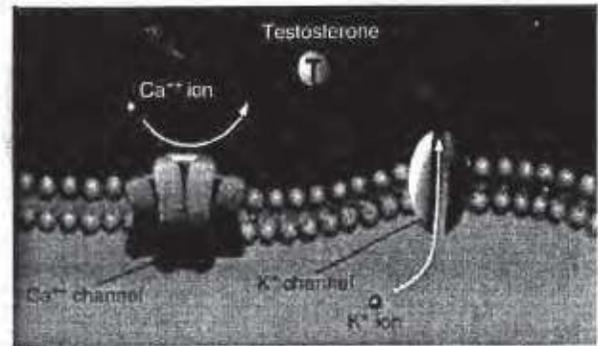

transdermal testosterone therapy improves exercise-induced myocardial ischemia (measured as time to ST depression) during an exercise stress test in men with stable angina,[22] with men having the lowest baseline testosterone levels benefitting the most. A recent study using oral testosterone in hypogonadal men with coronary artery disease showed increased myocardial perfusion.[23] These vasodilatory effects of testosterone are reflected by the fact that men with prostate cancer undergoing androgen depriva-tion therapy experience arterial stiffness.[24] It is believed that testosterone causes both endothe-lium-dependent and endothelium-independent va-sodilation. The former is achieved by an increased release of nitric oxide from endothelium, whereas the latter by blocking of calcium channels and/or opening of potassium channels[25] (Figure 1). Recent studies also suggest a beneficial role for testosterone in endothelial regeneration.[26] Testosterone replace-ment in hypogonadal men results in an increase in the number of circulating endothelial progenitor cells.[27] This increase is androgen receptor mediated (not a result of rise in estrogen levels) as this event is abolished by androgen receptor antagonists.[28]

Mortality

Recent population studies have shown that low serum testosterone levels are associated with both CV and all-cause mortality. A retrospective study of male veterans showed that low testosterone was associated with increased mortality.[29] A prospective study of 794 men, aged 50–91 years, looked at the relationship of testosterone with all-cause mortality over two decades.[30] Men with total testosterone levels in the lowest quartile (<241 ng per 100 ml) were 40% more likely to die than men with higher androgen levels, independent of age, adiposity, lipids, adipokines and lifestyle. In cause-specific analyses, low testosterone predicted increased risk

Figure 2 New spectrum of CV complications of low testosterone levels. CV, cardiovascular.

of mortality due to CV and respiratory disease. In a recent study, Khaw et al.[31] conducted a nested case–control study to determine the association of endogenous serum testosterone with all-cause, CV and cancer-related mortality. The authors compared 825 men who did not have any CV disease or cancer at baseline but died during the course of follow-up, with 1489 men who were still alive. The cases and controls were matched for age and date of baseline visit. The authors found that baseline testosterone levels were inversely related to deaths due to all cause, CV disease and malignancy. This protective effect of testosterone increased with increasing quartiles such that men in the highest quartile had 30% lower risk of death compared with those in the lowest quartile. Similarly, men undergoing androgen deprivation therapy for prostate cancer are also at risk of increased CV mortality compared with men not undergoing castration.[32]

Conclusion

This review shows that ample evidence has accumulated through epidemiological studies and small clinical trials showing that low androgen levels are associated with numerous CV risk factors and mortality (Figure 2). In addition to traditional CV risk factors, novel risk factors are also inversely related to testosterone levels. Indeed, a recent study showed that low testosterone levels increase oxidative stress in men and testosterone replacement reverses this pathology.[33] Similarly, the effect of testosterone treatment in men with chronic heart failure is also being explored.[34] Now what we need are long-term, double-blind, randomized, placebo-controlled trials of androgen replacement in men with low testosterone levels and evaluate its effect on CV risk factors, CV mortality and all-cause mortality. What we need is a Men's Health Initiative study and the federal funding agencies should be

open to this kind of trial. In the meantime, we should consider welcoming low testosterone as a new CV risk factor in men.

Conflict of interest

The authors declare no conflict of interest.

Testosterone Making an Entry Into the Cardiometabolic World

Shehzad Basaria, MD; Adrian S. Dobs, MD, MHS

From the Division of Endocrinology & Metabolism, The Johns Hopkins University School of Medicine, Baltimore, Md.

Correspondence to Adrian S. Dobs, MD, MHS, Division of Endocrinology & Metabolism, Johns Hopkins University School of Medicine, 1830 E Monument St, Suite 328, Baltimore, MD 21287. E-mail adobs@jhu.edu

Testosterone, the predominant sex hormone in men, is produced by the testes under stimulation by the gonadotrophs in the pituitary, which in turn are controlled by gonadotropin-releasing hormone neurons in the hypothalamus. A young adult man generally produces 3 to 10 mg of testosterone daily, which translates into serum values of 300 to 1000 ng/dL. The consequences of classical male hypogonadism (primary or secondary) have been long known to physicians and patients alike and include decreased libido, erectile dysfunction, osteoporosis, reduced sexual hair, and changes in body habitus. Recently, we have come to appreciate that reductions in serum testosterone resulting from aging or chronic disease have signs and symptoms similar to those seen in classical male hypogonadism, along with increased fat mass, decreased lean body mass, decreased muscle strength, and diminished quality of

life.[1] During the past decade, reports have been trickling in, mainly from laboratory and epidemiological studies (and a few clinical studies), linking differences in serum testosterone levels to various cardiovascular risk factors and also directly to cardiovascular disease and death. The article by Khaw et al[2] in this issue of *Circulation* is another link to this growing chain.

Article p 2694

Thirteen years ago, Phillips et al[3] reported that low total and free testosterone levels were inversely linked to coronary artery disease, even after adjusting for age and adiposity. This observation still holds true, as was recently supported by a study showing that men with angiographically proven coronary artery disease had lower levels of testosterone than those of controls.[4] Furthermore, testosterone levels were negatively correlated to the degree of coronary involvement. A few population-based studies have been published that relate low serum testosterone level with risk of death. A study of male veterans showed that low testosterone was associated with increased risk of death[5]; however, it was a retrospective study, and the subjects were a clinic-based Veterans Administration population, who tend to have greater medical morbidity, rather than healthy men living in the community. Recently, a prospective population-based study of 794 men, 50 to 91 years of age, in the Rancho Bernardo community, looked at the relationship of testosterone with all-cause death over the subsequent 2 decades.[6] The authors found that men whose total testosterone levels were in the lowest quartile, defined as <241 ng/dL, were 40% more likely to die than were men with higher androgen levels. These findings were independent of age, adiposity, lipids, adipokines, and lifestyle. In cause-specific analyses, low testosterone predicted increased risk of death due to cardiovascular and respiratory disease. The findings of this study are not surprising given the fact that low testosterone is independently associated with many of the individual risk factors for heart disease. For example, testosterone levels are inversely related to fat mass in men.[7] Indeed, men undergoing androgen deprivation for the treatment of prostate cancer have higher body mass index and fat mass than age and disease-matched controls.[8] This role of fat mass regulation by androgens is further supported by the fact that testosterone administration decreases adiposity in men.[9] Because fat mass is an independent predictor of cardiovascular death, it seems that testosterone is an important player in regulating this cardiovascular risk.

In addition to body mass index and fat mass, testosterone has been linked to other cardiovascular risk factors. The vascular system seems to be an important target of androgen action, and current evidence suggests that androgens are beneficial to the vascular system. Older clinical trials, though not as rigorously conducted, showed that testosterone replacement relieved symptoms of angina and peripheral vascular disease.[10] Almost half a century later, experimental studies showed that acute treatment with testosterone results in dilatation of the coronary arteries in animals.[11] Subsequently, a clinical trial showed that transdermal testosterone therapy improved exercise-induced myocardial ischemia (measured as time to ST depression) during an exercise stress test in men with stable angina.[12] These vasodilatory effects of testosterone on coronary and other vasculature are confirmed by the findings that men with prostate cancer undergoing androgen-deprivation therapy experience an increase in central arterial pressure (reflecting stiffening of large arteries).[13] Similarly, in population studies, systolic and diastolic blood pressures have been shown to be inversely correlated with testosterone level.[14]

In addition to vasomotor regulation, testosterone levels are also inversely related with arterial calcification. In the Rotterdam Study, the association between total and bioavailable testosterone with aortic atherosclerosis was evaluated in 504 nonsmoking men ≥55 years of age.[15] Compared with men with levels of total and bioavailable

testosterone in the lowest tertile, men in the highest tertile had a risk reduction of 60% to 80% of severe aortic atherosclerosis. Adjustments for age and cardiovascular risk factors did not influence these results. Given that aortic atherosclerosis was assessed by radiographic detection of calcification in the abdominal aorta, it is likely that subclinical atherosclerosis was not detected in this study. Another prospective study of elderly men (mean age 77 years) showed free testosterone concentration to be inversely related to the progression of intima-media thickness of the common carotid artery after adjustment for age and other risk factors.[16] Hence, it appears that arterial stiffening and increased atherosclerosis are 2 mechanisms by which male hypogonadism may contribute to high risk of death.

Another mechanism by which low testosterone may contribute to a higher death rate is its association with diabetes. Epidemiological studies show that low testosterone levels are independently associated with type 2 diabetes mellitus after adjusting for potential confounders.[17] In fact, lower concentrations of free and bioavailable testosterone even in the normal range are associated with diabetes, independent of adiposity.[18] Furthermore, low total testosterone levels independently predict development of the metabolic syndrome in middle-aged men.[19] A clinical model that further establishes the role of testosterone in the mediation of glucose metabolism is that of androgen deprivation in men with prostate cancer. It is seen that insulin resistance develops within a few months of initiation of androgen-deprivation therapy[13]; however, when men undergoing long-term androgen deprivation are studied, in addition to hyperinsulinemia, they have a higher prevalence of hyperglycemia and metabolic syndrome.[20,21] This relationship between hypogonadism and hyperglycemia persists even after adjustment for age and body mass index, and the degree of hyperglycemia is directly related to the duration of sex hormone suppression.[22] Thus, hypoandrogenism seems to be an early marker for disturbances in insulin and glucose metabolism and may contribute to the pathogenesis of diabetes and metabolic syndrome, thus again contributing to the cardiovascular risk.

Another risk factor linking hypogonadism to cardiovascular disease is the association of androgens with lipids and inflammatory cytokines. Epidemiological data suggest that testosterone levels are associated with a beneficial lipid profile, with negative correlations with total cholesterol, low-density lipoprotein cholesterol, and triglycerides and a positive association with high-density lipoprotein cholesterol.[23] Similarly, there are reports of inverse associations between inflammatory cytokines and testosterone.[24] These associations are further validated by clinical trials showing improvement in lipid profile and reduction in inflammatory cytokines with testosterone replacement.[25] Additionally, inverse associations between testosterone and plasminogen activator inhibitor I, fibrinogen, and factor VII have been reported in men.[15] Animal experiments also suggest beneficial effects of testosterone on plaque development.[26] In summary, these findings suggest that testosterone may influence cardiovascular disease via multiple mechanisms, including changes in body composition, fat metabolism, glucose regulation, vascular mechanisms, and clotting (see the Figure).

In this issue of *Circulation*, Khaw et al[2] provide more evidence that makes the chain linking low testosterone to risk of death even stronger.[2] The authors conducted a nested case–control study to determine the association of endogenous serum testosterone with all-cause, cardiovascular, and cancer-related death. The authors compared 825 men, who did not have any cardiovascular disease or cancer at baseline but died during the course of follow-up, with 1489 men who were still alive. The cases and controls were matched for age and date of baseline visit. The authors found that baseline testosterone levels were inversely related to deaths due to all causes, cardiovascular disease, and malignancy, after controlling for the usual confounders (plus dehydroepiandrosterone sulfate and sex hormone–binding globulin). This protective effect of testosterone increased with increasing quartiles, such that men in the highest quartile had a 30% lower risk of death than that of those in the lowest quartile. Even after excluding deaths during the first 2 years of follow-up, this inverse relationship was maintained. In fact, every 6-nmol/L (173-ng/dL) increase in serum testosterone decreased the death rate by 14%, and this benefit was irrespective of patient's age (above or below 65 years of age).

Though the study was well conducted, the findings should be interpreted with caution. First, the testosterone values were based on only a single measurement. Hence, one cannot control for any errors in measurement or transient variation in testosterone secretion. Second, the authors did not measure or calculate either free or bioavailable testosterone, the moiety that binds to the androgen receptor. These measures are more accurate than total testosterone, especially in subjects with obesity or diabetes and in older men because changes in sex hormone–binding globulin levels are expected in such patients. Finally, the authors did not measure estradiol levels. It would have been interesting to see whether these beneficial effects of testosterone are mediated by the testosterone itself or via aromatization to estradiol.

So is low serum testosterone just a marker for sickness (or wellness), or does it have a true pathogenic role? Even though Khaw et al[2] excluded men with serious disease and also those who died within the first 2 years of baseline visit (assuming that they may have had subclinical illness), the authors were cautious enough (rightly so) in mentioning that they still might have included men with subclinical disease. Nevertheless, on the basis of all the evidence cited in the present editorial, we believe that testosterone has a pathogenic role in the development of cardiovascular disease and is not simply a "marker" for illness and wellness. In terms of death related to cancer and respiratory disease (an association suggested by other reports),[27] the exact mechanism by which testosterone may cause an increased risk of death is currently unknown.

Hence, increasing evidence indicates that low androgen levels are associated with all-cause death and especially cardiovascular death. What do we do now on the basis of the reasonably substantial information discussed with regard to testosterone and cardiovascular disease? We believe the answer lies in long-term, double-blind, randomized, placebo-controlled trials of androgen replacement in men with low testosterone levels to evaluate its effects on cardiovascular disease, cardiovascular death, and all-cause death. We cannot assume that testosterone replacement will ameliorate the increased risk seen in these epidemiological studies. We still have not answered questions about the critical level for starting treatment, optimal dose, target testosterone level to be reached, or long-term safety. What we need is a Men's Health Initiative study. With all these data, androgens should no longer be considered as mediators of only sexual function or skeletal health, nor should they be discarded by defaming them as a "fountain of youth," as has been done by some critics of androgen replacement. The aim is to critically evaluate the effects of testosterone treatment by performing large trials, similar to those recently

Testosterone: a metabolic hormone in health and disease

Daniel M Kelly[1] and T Hugh Jones[1,2]

Abstract

Testosterone is a hormone that plays a key role in carbohydrate, fat and protein metabolism. It has been known for some time that testosterone has a major influence on body fat composition and muscle mass in the male. Testosterone deficiency is associated with an increased fat mass (in particular central adiposity), reduced insulin sensitivity, impaired glucose tolerance, elevated triglycerides and cholesterol and low HDL-cholesterol. All these factors are found in the metabolic syndrome (MetS) and type 2 diabetes, contributing to cardiovascular risk. Clinical trials demonstrate that testosterone replacement therapy improves the insulin resistance found in these conditions as well as glycaemic control and also reduces body fat mass, in particular truncal adiposity, cholesterol and triglycerides. The mechanisms by which testosterone acts on pathways to control metabolism are not fully clear. There is, however, an increasing body of evidence from animal, cell and clinical studies that testosterone at the molecular level controls the expression of important regulatory proteins involved in glycolysis, glycogen synthesis and lipid and cholesterol metabolism. The effects of testosterone differ in the major tissues involved in insulin action, which include liver, muscle and fat, suggesting a complex regulatory influence on metabolism. The cumulative effects of testosterone on these biochemical pathways would account for the overall benefit on insulin sensitivity observed in clinical trials. This review discusses the current knowledge of the metabolic actions of testosterone and how testosterone deficiency contributes to the clinical disease states of obesity, MetS and type 2 diabetes and the role of testosterone replacement.

Abstract

Metabolic syndrome and testosterone deficiency in men are closely linked.
Epidemiological studies have shown that low testosterone levels are associated with
obesity, insulin resistance and an adverse lipid profile in men. Conversely in men with
metabolic syndrome and type 2 diabetes have a high prevalence of hypogonadism.
Metabolic syndrome and low testosterone status are both independently associated with
increased all-cause and cardiovascular mortality. Observational and experimental data
suggest that physiological replacement of testosterone produces improvement in insulin
resistance, obesity, dyslipidaemia and sexual dysfunction along with improved quality of
life. However, there are no long-term interventional studies to assess the effect of
testosterone replacement on mortality in men with low testosterone levels. This article
reviews the observational and interventional clinical data in relation to testosterone and
metabolic syndrome.

Testosterone Replacement in Hypogonadal Men With Type 2 Diabetes and/or Metabolic Syndrome (the TIMES2 Study)

Abstract

OBJECTIVE This study evaluated the effects of testosterone replacement therapy (TRT) on insulin resistance, cardiovascular risk factors, and symptoms in hypogonadal men with type 2 diabetes and/or metabolic syndrome (MetS).

RESEARCH DESIGN AND METHODS The efficacy, safety, and tolerability of a novel transdermal 2% testosterone gel was evaluated over 12 months in 220 hypogonadal men with type 2 diabetes and/or MetS in a multicenter, prospective, randomized, double-blind, placebo-controlled study. The primary outcome was mean change from baseline in homeostasis model assessment of insulin resistance (HOMA-IR). Secondary outcomes were measures of body composition, glycemic control, lipids, and sexual function. Efficacy results focused primarily on months 0–6 (phase 1; no changes in medication allowed). Medication changes were allowed in phase 2 (months 6–12).

RESULTS TRT reduced HOMA-IR in the overall population by 15.2% at 6 months (P = 0.018) and 16.4% at 12 months (P = 0.006). In type 2 diabetic patients, glycemic control was significantly better in the TRT group than the placebo group at month 9 (HbA1c: treatment difference, −0.446%; P = 0.035). Improvements in total and LDL cholesterol, lipoprotein a (Lpa), body composition, libido, and sexual function occurred in selected patient groups. There were no significant differences between groups in the frequencies of adverse events (AEs) or serious AEs. The majority of AEs (>95%) were mild or moderate.

CONCLUSIONS Over a 6-month period, transdermal TRT was associated with beneficial effects on insulin resistance, total and LDL-cholesterol, Lpa, and sexual health in hypogonadal men with type 2 diabetes and/or MetS.

Abstract

A considerable body of evidence exists suggesting a link among reduced testosterone plasma levels, type 2 diabetes (T2D), and insulin resistance (IR). Hypogonadal men are at higher risk for T2D. Here we evaluate the relationships between testosterone, metabolic syndrome (MetS), T2D, and IR and discuss the relationships among androgen deficiency and these factors, especially as it ultimately relates to the development of cardiovascular disease and erectile dysfunction (ED). Thus, a comprehensive literature search was carried out using PubMed, and relevant articles pertinent to androgen deficiency, T2D, IR, MetS, and ED were reviewed and discussed. Low testosterone precedes elevated fasting insulin, glucose, and hemoglobin A1c (HbA1C) values and may even predict the onset of diabetes. Treatment of prostate cancer patients with surgical or medical castration exacerbates IR and glycemic control, strengthening the link between testosterone deficiency and onset of T2D and IR. Androgen therapy of hypogonadal men improves insulin sensitivity, fasting glucose, and HbA1c levels. We suggest that androgen deficiency is associated with IR, T2D, MetS, and with increased deposition of visceral fat, which serves as an endocrine organ, producing inflammatory cytokines and thus promoting endothelial dysfunction and vascular disease.

Abstract. Normal levels of male sex hormones are essential to men's health. Many studies demonstrate that hypogonadal men are at higher risk for developing a host of metabolic derangements, including dyslipidemia, type 2 diabetes mellitus, obesity, and hypertension. We examined the most recent studies supporting this notion of hypogonadism as a cardiac risk factor by reviewing all relevant PubMed data. Most studies showed an increase in metabolic disorders and cardiac events in hypogonadal men compared to their eugonadal counterparts. Mechanisms explaining this increased risk include adverse cytokine profiles produced by excess adipose tissue, abnormal lipid metabolism by understimulated hormone-sensitive lipase, and abnormal cellular respiration leading to insulin resistance. In contrast, some studies have not demonstrated such an increased cardiac risk. Conflicting data between studies is expected, given the complexity of testosterone and its metabolic effects. Additionally, the interaction of testosterone with the androgen receptor differs based on an individual genome. Hypogonadism will affect individual men differently because of this genomic variance. The literature points toward true hypogonadism as a major cardiac risk factor. Men at risk of being hypogonadal should be screened and brought back to eugonadism with hormone replacement.

Testosterone serves to maintain health in every system of the body. It is produced mainly in the Leydig cells of the testes in response to luteinizing hormone release from the pituitary gland. Testosterone acts on muscle, bone, bone marrow, testes, and the central nervous system through direct effects on target tissues, as well as through the effects of its metabolites estradiol and dihydrotestosterone (DHT). Estradiol is produced by the aromatase enzyme in adipose tissue and the more potent androgen DHT is produced by the 5-α reductase enzyme in prostate and skin (see Fig. 1).

Because of its diverse effects, the task of describing testosterone's cardiovascular effects may prove to be even more difficult than the female sex hormone estrogen. The Woman's Health Initiative (WHI) attempted to establish a beneficial role for estrogens in preventing heart disease, but instead discovered an increase in heart disease during the study. In parallel, testosterone, once believed to have negative effects on heart disease, is now emerging as essential to men's health, highlighting the importance of male eugonadism.

Abstract

In both men and women, circulating androgen levels decline with advancing age. Until now, results of several small studies on the relationship between endogenous androgen levels and atherosclerosis have been inconsistent.

In the population-based Rotterdam Study, we investigated the association of levels of dehydroepiandrosterone sulfate (DHEAS) and total and bioavailable testosterone with aortic atherosclerosis among 1,032 nonsmoking men and women aged 55 yr and over. Aortic atherosclerosis was assessed by radiographic detection of calcified deposits in the abdominal aorta, which have been shown to reflect intimal atherosclerosis.

Relative to men with levels of total and bioavailable testosterone in the lowest tertile, men with levels of these hormones in the highest tertile had age-adjusted relative risks of 0.4 [95% confidence interval (CI), 0.2–0.9] and 0.2 (CI, 0.1–0.7), respectively, for the presence of severe aortic atherosclerosis. The corresponding relative risks for women were 3.7 (CI, 1.2–11.6) and 2.3 (CI, 0.7–7.8). Additional adjustment for cardiovascular disease risk factors did not materially affect the results in men, whereas in women the associations diluted. Men with levels of total and bioavailable testosterone in subsequent tertiles were also protected against progression of aortic atherosclerosis measured after 6.5 yr (SD ± 0.5 yr) of follow-up (*P* for trend = 0.02). No clear association between levels of DHEAS and presence of severe aortic atherosclerosis was found, either in men or in women. In men, a protective effect of higher levels of DHEAS against progression of aortic atherosclerosis was suggested, but the corresponding test for trend did not reach statistical significance.

In conclusion, we found an independent inverse association between levels of testosterone and aortic atherosclerosis in men. In women, positive associations between levels of testosterone and aortic atherosclerosis were largely due to adverse cardiovascular disease risk factors.

Androgens and Diabetes in Men

Results from the Third National Health and Nutrition Examination Survey (NHANES III)

OBJECTIVE — Low levels of androgens in men may play a role in the development of diabetes; however, few studies have examined the association between androgen concentration and diabetes in men in the general population. The objective of this study is to test the hypothesis that low normal levels of total, free, and bioavailable testosterone are associated with prevalent diabetes in men.

RESEARCH DESIGN AND METHODS — The study sample included 1,413 adult men aged ≥20 years who participated in the morning session of the first phase of the Third National Health and Nutrition Examination Survey, a cross-sectional survey of the civilian, noninstitutionalized population of the U.S. Bioavailable and free testosterone levels were calculated from serum total testosterone, sex hormone–binding globulin, and albumin concentrations.

RESULTS — In multivariable models adjusted for age, race/ethnicity, and adiposity, men in the first tertile (lowest) of free testosterone level were four times more likely to have prevalent diabetes compared with men in the third tertile (odds ratio 4.12 [95% CI 1.25–13.55]). Similarly, men in the first tertile of bioavailable testosterone also were approximately four times as likely to have prevalent diabetes compared with men in the third tertile (3.93 [1.39–11.13]). These associations persisted even after excluding men with clinically abnormal testosterone concentrations defined as total testosterone <3.25 ng/ml or free testosterone <0.07 ng/ml. No clear association was observed for total testosterone after multivariable adjustment (P for trend across tertiles = 0.27).

CONCLUSIONS — Low free and bioavailable testosterone concentrations in the normal range were associated with diabetes, independent of adiposity. These data suggest that low androgen levels may be a risk factor for diabetes in men.

● ●

It has been suggested that sex steroid hormones may play a causal role in the development of insulin resistance and type 2 diabetes (1,2). There is a growing amount of literature examining the role sex steroid hormones may play in the development of diabetes and cardiovascular disease in women, but there has been relatively less attention paid to this association in men. Men with endocrine disorders that are associated with low testosterone levels (hypogonadism), such as Klinefelter's and Wolfram's syndromes, have an elevated risk of developing insulin resistance and diabetes (3,4). However, the association between sex steroid concentrations within the normal range and diabetes risk in men in the general population has not been well characterized.

Obesity, one of the most important underlying causes of insulin resistance, is associated with low testosterone levels in men (5–7) and may partially or wholly mediate the process by which endogenous sex hormones influence diabetes risk. Many previous studies have been conducted in small, highly selected populations or convenience samples and/or did not rigorously measure or control for the possible effects of adiposity. The present study was undertaken to investigate the association between sex steroid hormones and diabetes in the general adult male population in the U.S. Specifically, we hypothesized that low levels of total, free, and bioavailable testosterone would be associated with prevalent diabetes. We also hypothesized that this association would persist after controlling for the potentially confounding effects of adiposity. Estimates from this study are nationally representative of the U.S. adult male population in 1988–1991.

RESEARCH DESIGN AND METHODS — Between 1988 and 1994, the National Center for Health Statistics conducted the Third National Health and Nutrition Examination Survey (NHANES III). NHANES III was designed as a cross-sectional study using a multistage-stratified, clustered probability sample of the U.S. civilian noninstitutionalized population. To ensure adequate

Free testosterone and risk for Alzheimer disease in older men

Abstract—*Objective:* To investigate the relationships between age-associated decreases in endogenous serum total testosterone (T) and a free T index (FTI) in men and the subsequent development of Alzheimer disease (AD). *Method:* The authors used a prospective, longitudinal design with follow-up in men since 1958. Participants were from the Baltimore Longitudinal Study of Aging, a community-dwelling volunteer sample with baseline ages of 32 to 87 years. All subjects were free of AD at baseline T assessment. Five hundred seventy-four men assessed at multiple time points were followed for a mean of 19.1 years (range, 4 to 37 years). Diagnoses of AD were based on biennial physical, neurologic, and neuropsychological evaluations. *Results:* Diagnosis of AD was associated inversely with FTI by itself and after adjustments for age, education, smoking status, body mass index, diabetes, any cancer diagnoses, and hormone supplements. In separate analyses, total T and sex hormone binding globulin were not significant predictors after adjustment with covariates. Increases in the FTI were associated with decreased risk of AD (hazard ratio = 0.74; 95% CI = 0.57 to 0.96), a 26% decrease for each 10-nmol/nmol FTI increase. *Conclusions:* Calculated free testosterone concentrations were lower in men who developed Alzheimer disease, and this difference occurred before diagnosis. Future research may determine whether higher endogenous free testosterone levels offer protection against a diagnosis of Alzheimer disease in older men.
NEUROLOGY 2004;62:188–193

A sizable literature now exists relating age-related alterations in the endocrine environment to cognitive changes[1-3] and the onset of Alzheimer disease (AD) in women.[4-7] The comparative dearth of similar research in men may be attributable primarily to the fact that testosterone replacement therapy (TRT) has been used much less commonly in men than hormone therapy in women. Moreover, TRT has not been administered for time periods that are sufficiently long to establish linkages to AD. Nevertheless, androgen levels in men decrease substantially with age, raising the question of whether this decrease may contribute to the development of AD.[8,9] Although numerous studies have demonstrated contributions of testosterone (T) to selected cognitive functions in young[10-12] and old men,[13-15] to date there have been no studies assessing prospectively the risk for AD associated with the so-called "andropause."

Decreased total T levels have been reported in men with AD compared with age-matched control subjects.[16] However, these data are ambiguous because the depleted T levels may be a consequence rather than a cause of the disease. To assess the impact of T decline in the subsequent manifestation of AD, it is essential to obtain measures of T that *precede* the development of the disease.

In the present study, we followed 574 men whose ages at baseline T assessment ranged from 32 to 87 years for a mean duration of 19.1 years. We collected multiple serum samples for determination of total T, sex hormone binding globulin (SHBG), and the calculated free T index (FTI) and evaluated presence or absence of a diagnosis of AD as the principal outcome variable. We report here the first prospective longitudinal study assessing the impact of long-term total and estimated free T levels on the development of AD.

Methods. *Subjects.* Subjects were men who volunteered to participate in the Baltimore Longitudinal Study of Aging (BLSA), a study performed by the National Institute on Aging (NIA).[17] Participants were community dwelling and returned every 2 years to the Gerontology Research Center of the NIA for comprehensive medical and neuropsychological evaluations. Androgen data were available for a large number of BLSA men whose blood samples were assayed as part of a study of prostate health and disease.
